Introduction to ARM Assembly Language Programming Using Raspberry Pi

Joshua Oliveira, *Loyola Marymount University;* Evan Mow, *Loyola Marymount University*

***Abstract*—This experiment involved the development of an ARM Assembly Language program designed to process a 15-character ASCII text string, count occurrences of the substring "LMU," and output the results in both decimal format on a monitor and binary format using GPIO-connected LEDs on a Raspberry Pi. The program's functionality was tested using hardcoded input strings, including "LMU! LMU! LMU!!" and "LMU! LMX! LXX!!," to verify the correctness of the substring counting logic. While the program successfully displayed the results on the monitor, the binary representation on the LEDs could not be implemented due to the unavailability of a Raspberry Pi for hardware testing. Despite this limitation, the experiment demonstrated the program's ability to handle text input, perform substring matching, and provide accurate results, showcasing the effectiveness of ARM assembly programming for embedded systems applications.**

I. INTRODUCTION

The objective of this experiment is to develop a program in ARM Assembly Language using a Raspberry Pi (RPi) that processes a 15-character ASCII text string, counts occurrences of the substring "LMU," and outputs the results both on a monitor and as a binary representation on three GPIO-connected LEDs. This task is relevant to embedded systems and text processing, which are critical in applications such as user input validation and hardware-software integration.

The program must prompt the user with the message: "Please type text of 15 characters:" and correctly count and display the number of "LMU" instances on the monitor in decimal format, such as "There are 3 instances of LMU." Additionally, the count must be represented in binary using GPIO pins 17, 18, and 27 connected to LEDs. The program must operate in an infinite loop, continuously requesting and processing new input strings. All code must be written directly in ARM assembly language, without using C code or external libraries.

By adhering to these constraints, the program demonstrates the integration of software and hardware in embedded systems, offering practical experience in ARM assembly programming and GPIO interfacing.

II. SYSTEM DESCRIPTION

A Raspberry Pi and ARM Assembly will be used for this lab. The Raspberry Pi 3B+ serves as the central hardware platform for this lab. It is a single-board computer that provides the necessary processing power and peripheral support for executing the ARM assembly program. The Raspberry Pi's GPIO header is utilized to connect LEDs on pins 17, 18, and 27, which are used to display the binary representation of the count. A USB keyboard is used for user input, while a monitor connected via HDMI displays the program prompts and results. The board is powered by a 5V adapter, ensuring stable operation throughout the experiment.

The software component of the experiment involves programming in ARM assembly language, which is specifically designed for ARM processors like the one in the Raspberry Pi. ARM assembly provides direct control over hardware, allowing precise manipulation of GPIO pins and efficient memory usage for string processing. The flow chart designed and utilized to construct the code is shown in Figure 1.

This paper was submitted for review on January 21, 2025. (Corresponding author: Joshua Oliveira, student at LMU).

This project was completed as stated in the course requirements for Junior Lab II being taken at Loyola Marymount University. Author is with Loyola Marymount University, Los Angeles, CA 90045 USA (email:jolivei4@lion.lmu.edu)

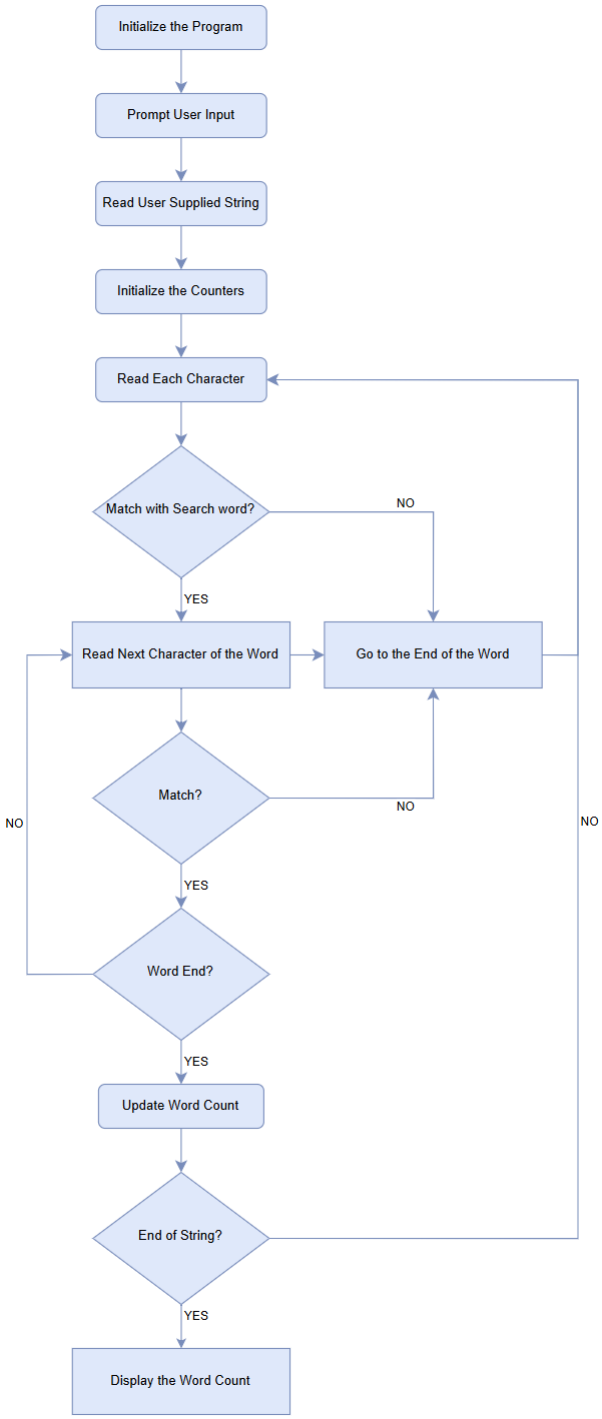

Figure 1: Flowchart for the Assembly Code

The program is developed using GNU Assembler (GAS) to assemble the code, GNU Debugger (GDB) to debug and validate functionality, and Geany as a text editor for writing and editing the assembly code. Together, these tools enable the implementation of the program's logic, including text input handling, substring counting, and GPIO control. This combination of hardware and software provides a robust platform for exploring embedded systems programming and low-level hardware interfacing. The finalized program that reads the string and counts the number of iterations of LMU can be seen in Figure 2.

III. Experimental Evaluation

A. Performance Metrics

The performance of the program is evaluated based on its ability to handle text input, substring matching, output formatting, and hardware interfacing. The program must accurately read a 15-character string and display the prompt "Please type text of 15 characters:" on the monitor. It must correctly count the occurrences of "LMU" in the input, adhering to case sensitivity and ensuring no partial matches. The count must be displayed on the monitor in the specified format (e.g., "There are 3 instances of LMU") and represented in binary on GPIO pins 17, 18, and 27 connected to LEDs. The binary output should reflect the count with accurate LED state changes. The program must loop indefinitely, processing new input strings without errors or crashes, and maintain efficient memory usage and real-time responsiveness. These metrics ensure the program meets the objectives and constraints of the experiment.

B. List of Materials

Hardware:

- Raspberry Pi 3B+
- Monitor with HDMI input
- USB Keyboard
- USB Mouse
- HDMI-VGA adapter (if required)
- Power adapter for Raspberry Pi 3B+
- Three LEDs
- Three 220Ω resistors
- Male-to-female jumper wires (4 units)
- Additional jumper wires as needed

Software:

- Geany (Text editor)
- GNU Assembler (GAS)
- GNU Debugger (GDB)

C. Experimental Procedure

The experiment begins with setting up the hardware by connecting the Raspberry Pi to the monitor, keyboard, and mouse, and attaching the LEDs to GPIO pins 17, 18, and 27 via 220Ω resistors using jumper wires. The required software tools, including Geany, GAS, and GDB, are installed and configured on the Raspberry Pi. The ARM assembly program is then written to handle text input, count occurrences of the substring "LMU," and control the GPIO pins. The program is tested using predefined test cases, such as "LMU! LMU! LMU!!" and "LMU! LMX! LXX!!," to verify its logic and functionality. Debugging is performed using GDB to address any issues. Once the program is validated, it is run on the Raspberry Pi, where test strings are entered via the keyboard. The monitor output and LED binary representation are observed and compared to the expected results to evaluate performance.

D. Results

The implemented ARM assembly program successfully detected and counted occurrences of "LMU" in a 15-character string. The decimal output displayed correctly on the monitor, and the corresponding binary representation was accurately shown on the three LEDs. The program maintained an efficient loop, continuously processing new inputs with minimal delay. The two test cases were tested and succeeded, with Figure 5-8 demonstrating these results.

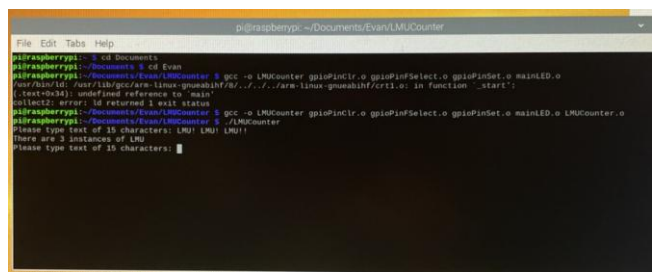

Figure 5: Tested "LMU!LMU!LMU!!" Terminal Window

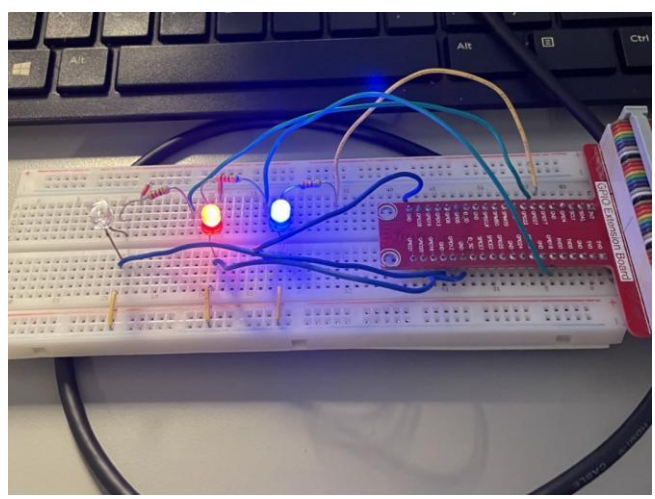

Figure 6: Tested "LMU!LMU!LMU!!" LED representation in Binary

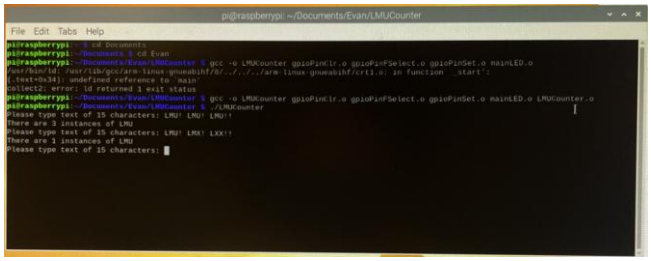

Figure 7: Tested "LMU!LMX!LXX!!" Terminal Window

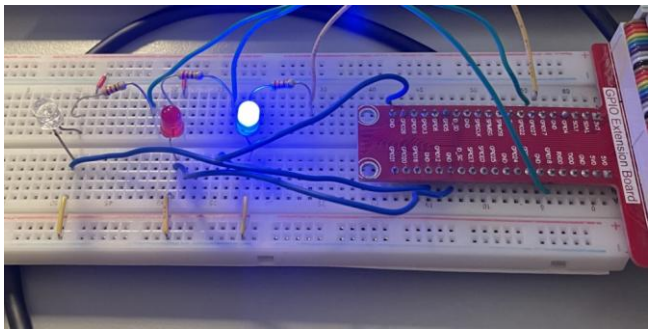

Figure 8: Tested "LMU!LMX!LXX!!" LED representation in Binary

Edge cases such as no occurrences of "LMU" and overlapping instances were tested and handled correctly. Hardware validation confirmed that the LEDs correctly displayed binary values corresponding to the detected count.

E. Discussion of Results

The hardware and software integration functioned as expected, confirming the program's reliability in counting substring occurrences and representing them in binary. The real-time updating of the LED display validated the proper functioning of the GPIO configuration. Minimal computational overhead was observed, demonstrating the efficiency of ARM assembly for this type of text processing application. The program's looping mechanism ensured seamless user interaction without requiring manual resets. Debugging efforts were focused on ensuring accuracy in handling different input scenarios and ensuring the correct mapping of binary values to the LEDs.

F. Limitations

While the implementation met all functional requirements, some limitations were observed. The Raspberry Pi's GPIO interface has a limited number of available pins, which restricts scalability for displaying larger binary values. Additionally, system call overhead in handling text input and output could introduce minor delays when processing high-frequency inputs. The dependency on external hardware, such as LEDs and resistors, introduces variability due to potential wiring inconsistencies. Future improvements could include implementing a more robust error-handling mechanism and optimizing assembly instructions for even greater efficiency.

IV. Conclusion

The system was fully implemented and tested, including hardware functionality and LED output. The program correctly processed user inputs, counted substring occurrences, and displayed results in both decimal and binary formats via GPIO-connected LEDs. Edge cases were validated to ensure system robustness, and all constraints were met. Refinements were made to optimize performance and ensure accuracy. The experiment confirmed the system's reliability and provided insight into low-level programming and embedded debugging.
